Abstract

Silica aerogel has been extensively used in RICH detectors for the identification of charged particles over the momentum range 1 GeV/c to a few GeV/c. Tiles of hygroscopic aerogel with large transverse dimensions (20×20 cm\textsuperscript{2}) and refractive index $n = 1.03$ have recently been produced for use in the LHCb experiment, allowing pion–kaon identification up to 10 GeV/c. The tiles have excellent optical properties (clarity factor better than 0.006 $\mu m^4$/cm and homogeneity $\sigma(n - 1)/(n - 1) \sim 1\%$ within the tile). Extensive R&D tests on aerogel samples have been performed. Samples have been exposed to intense irradiation (proton, neutron and gamma), to humid air, to standard black varnish (used to paint the inner surface of RICH detectors), and to C\textsubscript{4}F\textsubscript{10} and CO\textsubscript{2} gases. The optical properties of the aerogel have been monitored during these tests and, when required, recovery procedures have been investigated and applied. In particular, regeneration of the tiles has been realized through exposure to dry atmosphere (gaseous N\textsubscript{2}) or through baking for several hours at 500 °C. The measurements demonstrate that the optical properties have been successfully restored to their values at the production stage, and in no case permanent degradation has been observed.

Proceedings presented at the 
6\textsuperscript{th} International Workshop on Ring Imaging Cherenkov Counters (RICH2007) 
Trieste (Italy)
1 Introduction

Particle identification over the momentum range 1–60 GeV/c will be performed in the LHCb experiment [1] using the RICH1 detector [2, 3]. RICH1 is equipped with two Cherenkov radiators, solid silica aerogel and gaseous C\textsubscript{4}F\textsubscript{10}. The aerogel samples have been produced by the Boreskov Institute of Catalysis (Novosibirsk).

Silica aerogel is a solid material made of SiO\textsubscript{2} with a very low density. Due to its transparency and its refractive index which is tunable within a wide range to match the physical requirements, it is an appealing material for RICH detectors. The refractive index is tuned during production by calibrating the density.

Photon scattering within the aerogel block limits the performance of this material as a Cherenkov radiator. The dominant contribution comes from the Rayleigh scattering mechanism with a cross section proportional to $\lambda^{-4}$, where $\lambda$ is the photon wavelength. The transmittance $T(\lambda)$ is parameterized by:

$$T(\lambda) = A \ e^{-C t \lambda^{-4}}$$  \hspace{1cm} (1)

where $t$ is the thickness of the block and $A$ is a constant for the material, which is wavelength–independent. The clarity factor $C$ is used to specify the optical quality of the sample.

The RICH1 solid Cherenkov radiator consists of a wall of 50 mm thick hygroscopic aerogel tiles. The aerogel refractive index $n$ is 1.030, with exceptionally good clarity, typically $C = 0.0050 \mu m^4/cm$ or better. The LHCb tiles have the largest transverse size ever produced, up to $200 \times 200$ mm\textsuperscript{2}.

2 Ageing effects and long–term stability

Due to its position inside the detector, the aerogel radiator will be exposed to a significant particle flux, up to $3.5 \times 10^{12}$ particles/cm\textsuperscript{2}/year. Possible ageing of aerogel due to intense irradiation has been investigated [4]. Aerogel tiles have been exposed to very intense $\gamma$ radiation from a $^{60}$Co source (dose up to $\sim 230$ kGy corresponding to about 30 years of data taking) and to proton and neutron high intensity beams (fluence up to $5.5 \times 10^{13}$ particles/cm\textsuperscript{2}). The transmittance has been monitored, studying the clarity factor as a function of the increasing dose of irradiation. No detectable degradation of the optical parameters was observed for $\gamma$ and proton irradiation. However a small worsening of the clarity due to neutron irradiation has been observed. For a fluence corresponding to the LHCb lifetime, the clarity factor in this case increases by about 5%. However this is not a concern for the particle identification performance.

The behaviour of hygroscopic aerogel when exposed to humid air has also been explored [4]. Here a modification of the aerogel optical properties is expected. The tests revealed that a prolonged exposure to humid air changes the optical properties of the aerogel, but the clarity can be completely restored by baking the exposed sample at high temperature. The integration of the aerogel into the RICH 1 detector will therefore be done with special care to prevent humidity absorption.

Inside the RICH1 detector volume, the aerogel radiator will be in contact with the gaseous C\textsubscript{4}F\textsubscript{10} radiator. Generally, air fills the porous structure of the aerogel solid, and a replacement of air with C\textsubscript{4}F\textsubscript{10} is expected. Possible effects have been investigated. Several
As shown in Fig. 1, the clarity coefficient rises with $C_4F_{10}$ exposure time, with a corresponding decrease in the photoelectron yield. Following this rise, between day 281 and 310, the tile was kept in a dry $N_2$ atmosphere to check the possibility of restoring the aerogel to its initial optical conditions. The $N_2$ regeneration demonstrates that there is no permanent degradation of the clarity. On resumption of the $C_4F_{10}$ exposure, it can be seen that the clarity again degrades, before reaching stability. The $N_2$ regeneration procedure is then repeated successfully at the end of the test.
Figure 3: Trial installation of the aerogel support mechanics into the RICH 1 detector.

Natural ageing variations have been studied by monitoring a tile kept in a humidity–controlled laboratory. The typical relative humidity of the air within the lab was in the range 15%–35%. Results are reported in Fig. 2. During four years of monitoring, the clarity variation is $\sim$4% per year. The fluctuations of $n$ and $C$ can be ascribed to uncontrolled absorption of water vapour or rejection of humidity previously absorbed, depending on the relative humidity level of the lab during measurements. The seasonal modulation is well described by the function:

$$y(t) = (p_0 t + p_1) + p_2 \cdot \sin (p_3 t + p_4)$$ (2)

where $y(t)$ can be either the clarity factor or the refractive index. The $p_3$ parameter is the frequency of the oscillatory pattern measured during the test. For the clarity factor, the period of the oscillatory pattern is $T = 2\pi/p_3 = (368 \pm 26)$ days, in good agreement with the seasonal hypothesis. The initial optical quality of this sample has been restored by baking.

3 Integration of Aerogel in the Detector

The RICH 1 detector is constructed around a gas– and light–tight vessel in which both the solid and the gaseous radiators are placed. Fig. 3 shows the internal part of the gas enclosure during a trial installation of the aerogel support mechanics. The inside of the enclosure is painted with black varnish\(^1\) to avoid unwanted reflections of Cherenkov photons. The aerogel is exposed to possible residual outgassing of the varnish inside the vessel.

A compatibility test of the aerogel with varnish vapours was performed by monitoring both the refractive index and the aerogel transmittance as a function of time. An aerogel tile was kept in a box which has been painted black inside. To speed up the test, the aerogel was in contact with the painted surfaces and the box was locked with screws. This set–up corresponds to a more hostile environment than will be experienced in the final RICH 1 detector.

\(^1\)The varnish is a “JalPrim Fond Adherent, Noir Mate”, produced by Jallut S.A. Peintures.
Figure 4: The variation of clarity factor (top) and refractive index (bottom) as a function of time during the black varnish compatibility test. The refractive index has been measured at $\lambda = 543.50$ nm. During this test, the aerogel block was in contact with the black varnish.

Figure 5: Example of a temperature cycle during the recovery procedure used for one of the tested aerogel tiles.

Fig. 4 shows the behaviour of the clarity factor and the refractive index as a function of exposure time to the black varnish. There is a variation of the clarity factor of the order of 70% over 425 days. The refractive index experiences a 0.1% variation, which is negligible.

At the end of the test, the tile was baked for several hours at 500 °C, and the clarity factor and the refractive index were re-measured. A typical temperature cycle used in the recovery process is shown in Fig. 5. The values of $C$ and $n$ are compatible with the ones measured at the beginning of the test, hence no permanent degradation has been detected.

Since the aerogel will at no time be in contact with the varnish inside RICH1, and also there will be a break of over 12 months before the aerogel is installed into the gas enclosure which will allow time for the varnish to outgas, a more realistic compatibility test was performed. In this test the aerogel block was not in contact with the varnish, and a realistic period for the varnish to outgas was allowed to elapse. After $\sim$200 days of
exposure, both \( C \) and \( n \) were found to be stable.

4  Compatibility of aerogel with \( \text{CO}_2 \) gas

During any scheduled LHC shutdown, the RICH1 gas enclosure will be filled with \( \text{CO}_2 \) instead of \( \text{C}_4\text{F}_{10} \). This is both to conserve the fluorocarbon gas radiator during periods of inactivity and to preserve a dry atmosphere inside the gas enclosure itself. A compatibility test of silica aerogel with \( \text{CO}_2 \) has therefore been performed in which an aerogel block was kept for several weeks in a gas-tight \( \text{CO}_2 \)-filled box. As expected, no visible variations were detected.

5  Conclusions

Extensive ageing and robustness tests have been performed on silica aerogel to assess its compatibility with the LHCb RICH1 environment. All relevant optical parameters have been monitored. The radiation hardness of the aerogel and its compatibility with \( \text{C}_4\text{F}_{10} \) and black varnish have been proven. No permanent degradation of the excellent optical properties has been detected in any of the performed tests. Recovery procedures such as exposure to dry atmosphere (gaseous \( \text{N}_2 \)) or baking at 500 °C have shown that the original quality of the exposed samples have been restored.

The production of all the 16 tiles required for the LHCb experiment is now complete and the tiles are ready to be installed in the LHCb RICH1 detector.
